Hepatitis C Virus Infected Human Megakaryocytes and Platelets: Intra-and Extracellular Evaluation

By Caroline Mitiká Watanabe, Nathália Almeida Souza Tancler, Aline Márcia Marques Braz, Shelly Favorito de Carvalho, Giovanni Faria Silva, Maria Inês de Moura Campos Pardini, Maria Aparecida Custodio Domingues, Guilherme Targino Valente, Paulo Eduardo de Abreu Machado, Rejane Maria Tommasini Grotto & Marjorie de Assis Golim

Abstract- This study aimed to determine whether the hepatitis C virus (HCV) infects human megakaryocytes and platelets and to measure the expression of receptors involved in virus-cell interaction. Platelets from healthy donors were infected with HCV in vitro and analyzed for viral expression and the receptors claudin-1 and cluster of differentiation 81 (CD81). HCV was detected on the surface and cytoplasm of both cells; cytoplasmic expression was higher compared to the surface. Platelets presented a claudin-1+/CD81- phenotype, and megakaryocytes showed a claudin-1+/CD81+ phenotype. We conclude that megakaryocytes and platelets are susceptible to HCV infection, regardless of CD81 expression, and megakaryocytes may serve as possible sites of viral replication.

Hepatitis C Virus Infected Human Megakaryocytes and Platelets: Intra-and Extracellular Evaluation

Caroline Mitiká Watanabe, Nathália Almeida Souza Tancler, Aline Márca Marques Braz, Shelly Favorito de Carvalho, Giovani Faria Silva, Maria Inês de Moura Campos Pardini, Maria Aparecida Custodio Domingues, Guilherme Targino Valente, Paulo Eduardo de Abreu Machado, Rejane Maria Tommasini Grotto & Marjorie de Assis Golim

Abstract - This study aimed to determine whether the hepatitis C virus (HCV) infects human megakaryocytes and platelets and to measure the expression of receptors involved in virus-cell interaction. Platelets from healthy donors were infected with HCV in vitro and analyzed for viral expression and the receptors claudin-1 and cluster of differentiation 81 (CD81). HCV was detected on the surface and cytoplasm of both cells; cytoplasmic expression was higher compared to the surface. Platelets presented a claudin-1+/CD81- phenotype, and megakaryocytes showed aclaudin-1+/CD81+ phenotype. We conclude that megakaryocytes and platelets are susceptible to HCV infection, regardless of CD81 expression, and megakaryocytes may serve as possible sites of viral replication. Furthermore, megakaryocytes may transfer the virus during thrombopoiesis, releasing infected platelets that may be carriers of extrahepatic viruses. The presence of HCV in megakaryocytes and platelets may be related to thrombocytopenia.

Keywords: viral infection, megakaryocytes, platelets, hepatitis C virus, chronic hepatitis C.

I. INTRODUCTION

Despite significant advances in the treatment of chronic hepatitis C with direct-acting antiviral therapy [1,2], approximately 290,000 people died from disease complications in 2019, mainly from causes related to cirrhosis and hepatocellular carcinoma. Around 58 million people chronically carry the hepatitis C virus (HCV), and annually it is reported 1.5 million new cases. Therefore, hepatitis C is still a global public health problem [3].

HCV is hepatotropic and mainly targets hepatocyte cells. However, extrahepatic viral locations are reported in endothelial cells [4], gastrointestinal mucosal cells [5], fibroblasts [6], macrophages, dendritic cells [7-11], erythrocytes [12], peripheral blood mononuclear cells (especially B- and T-lymphocytes, monocytes [13]), platelets [13;14] and megakaryocytes [2]. The existence of extrahepatic reservoirs may help to understand the symptoms or extrahepatic manifestations that patients develop. Moreover, extrahepatic reservoirs may be related to the high rate of chronic infection [2,4,14-17]. Thrombocytopenia is a common extrahepatic manifestation among patients with chronic hepatitis C, particularly those with long-term complications. This condition increases the risk of bleeding and complicates liver biopsies, which leads to compromised patient follow-up [18,19]. Acquired thrombocytopenia is triggered by several causes, including diseases caused by infectious agents such as HCV, HIV, and Helicobacter pylori [20,21]. The pathophysiology of thrombocytopenia may involve factors such as increased platelet destruction, decreased platelet production, bone marrow suppression, hypersplenism (including platelet sequestration in the enlarged spleen secondary to portal hypertension), autoimmunogenicity, thrombopoietin production imbalance, and adverse therapeutic effects [18,22].

HCV’s presence in bone marrow [22] and platelets [23] suggests these areas as biological compartments for the virus. Thrombocytopenia in chronic hepatitis C patients is associated with HCV’s infection of, or adherence to, platelets [14,23]. This interaction impairs both platelet function and the production of megakaryocytes, which are essential for platelet formation [2,25]. Platelet recovery after viral suppression/eradication further indicates the involvement of virus-platelet interactions in thrombocytopenia [20]. Patients with chronic hepatitis C also present alterations in the bone marrow microenvironment. Patients with a high viral load present hypo- and hypercellularity associated with sedimentation of immune complexes and peripheral cytopenia [22]. However, the exact mechanism of the HCV interaction with platelets—whether the virus only adsorbs to the platelet membrane or is internalized there—is poorly understood. Additionally, the virus can infect megakaryocytes in the bone marrow, transferring to platelets during thrombocytogenesis. Evidence of HCV in bone marrow [22] and platelets [23], along with...
supplemented with L-glutamine and 1% antibiotics (Gibco).

c) In vitro infection of megakaryocytes and platelets

For in vitro megakaryocyte infection, 4x10^6 nucleated cells of the enriched megakaryocyte pellet were resuspended in 1 ml of RPMI 1640 medium. Then 6mL of HCV plasma genotype 1 (100,000 viral RNA copies/mL) was added to the flask culture. Cells were incubated for 36 hours in a conventional cell incubator (Thermo Fisher) at 37°C in 5% CO₂. During the infection period, the cell culture was or bitally agitated (18 hours) without changing the culture medium. HCV-negative plasma was used as a control.

In vitro platelet infection was performed as described by Padovani et al. [14]. Briefly, 1 mL of resuspended platelets was incubated with 1 mL of genotype 1 HCV plasma containing 100,000 RNA copies/mL from patients with positive RT-PCR. Samples were incubated in a shaker (New Brunswick Scientific) for 48 hours at 37°C with continuous shaking at 10xg.

d) Assessment of HCV infectivity in megakaryocytes and platelets

The presence of HCV in megakaryocytes and platelets was examined following in vitro infection. This analysis was conducted using flow cytometry and confocal microscopy. The purpose of these assessments was to confirm the susceptibility of these cells to the virus and to determine the viral location. For HCV detection, we used the monoclonal antibody NS4A-FITC (clone S4-13 - Abcam), a protein common to all HCV genotypes [29]. Molecular biological assay was performed only in megakaryocytes, since previous study has shown HCV RNA expression in platelets, as described in Padovani et al. [14].

i. Flow cytometry analysis

Following infection, megakaryocyte cells were labeled with anti-human-CD61-PE (VIPL2 clone, EXBIO) and anti-CD45-PerCP (HI30 clone, BD Pharmingen) [26]. To label platelets, we used only the anti-human-CD61-PE (VIPL2 clone, EXBIO), a commonly used marker for both platelets and megakaryocyte cells. The presence of HCV was evaluated using the monoclonal anti-hepatitis C virus antibody NS4A-FITC (S4-13 clone - Abcam). Cells were incubated for 30 minutes at room temperature in the dark, according to the manufacturer’s instructions. In this assay, the control group comprises megakaryocyte cells incubated with plasma without HCV. Peripheral platelets obtained from HCV patients (n=2) were used to compare the virus behavior in vitro and in vivo. To detect HCV, we first labeled the surface of megakaryocyte and platelet cells. Then, we fixed the cells with 4.2% paraformaldehyde for 30 minutes at room temperature. Both cell types were permeabilized with 0.4% Triton X-100 for 5 minutes at room temperature and then stained with anti-NS4A. During the
steps, we washed the cells with the respective buffers following the rotation described above. To prevent the formation of platelet clots, polystyrene tubes were coated with 22% bovine albumin [30]. We obtained both cell types using a FACSCalibur™ device (BD Bioscience) and analyzed the results using CellQuest™ and FlowJo™ software (BD Bioscience). 50,000 events were collected at the CD61+ gate for all samples. The isotype controls were conducted following the experimental protocol and included Mouse IgG1-FITC (clone MOPC-21), Mouse IgG1-PerCP (clone MOPC-21), and Mouse IgG1-APC (clone MOPC-21 - BD Pharmingen).

The intra- and extracellular expression of HCV antigen (NS4A) was determined by comparing the mean fluorescence intensity (MFI - absolute number) values using the flow cytometry crossmatch assay model[28]. Expression index value >1.0 indicates intracellular expression due to the increase in fluorescence compared to surface expression.

ii. **Indirect immunofluorescence staining of HCV-infected cells (confocal microscopy)**

Twenty-five microliters of labeled megakaryocytes and platelets were applied to silanized HDA slides and covered with Fluoroshield histology mounting medium (F6182-Sigma-Aldrich). The slides were sealed with resin, stored at 6°C ± 2°C, and protected from light. Paraffin-embedded liver fragments from HCV-positive patients’ biopsies were used as a positive control in this experiment. First, paraffin-embedded liver tissues were sectioned at a thickness of 0.3μm and fixed onto silanized HDA slides. The slides were then incubated using an antigen retrieval PT Link device (Dako) for 60 minutes at 65°C in a histological incubator at the Immunohistochemistry Laboratory of the Department of Pathology of the Clinical Hospital of the Botucatu Medical School - UNESP. To block non-specific binding, avidin and biotin (Vector Laboratories) were applied to coverslip slides for 20 minutes at room temperature. The slides were washed with PBS and labeled for two hours at room temperature with anti-human CD61-PE diluted 1:50 with EnVisionTM FLEX Antibody Diluent (Dako). After labeling, slides were washed and incubated overnight with EnVisionTM diluted monoclonal anti-hepatitis C virus antibody NS4A-FITC diluted 1:20. Then, the slides were covered with Fluoroshield Histology Mounting Medium (Sigma-Aldrich) and kept at 4°C until confocal analysis. Images were taken using the TCS SP5 - Leica Laser Scanning Confocal Microscope, using the LAS AF software version 2.7.3.9723, available at the Electronic Microscopy Center of the Botucatu Institute of Biosciences, UNESP.

iii. **Detection of HCV RNA in megakaryocytes using real-time quantitative reverse transcription polymerase chain reaction (RT-qPCR)**

Part of the megakaryocyte-enriched cell suspension was divided equally. Tube 1 (negative control) was incubated with 1 mL of HCV-negative plasma. Tube 2 (test condition) had megakaryocyte added to RPMI and incubated with a pool of plasma containing 100,000 IU/mL of HCV genotype 1. Tube 3 (negative control) had 1 mL of the 100,000 IU/mL HCV genotype 1 plasma pool. The purpose of the final control assay was to prevent the adsorption of RNA present in the plasma in the tube; therefore, no megakaryocyte cells were added. The tubes were washed five times to remove any free virus that did not aggregate in the cells. All supernatants from each step were collected and frozen at -80°C for subsequent quantification of HCV RNA by qRT-PCR using the Abbott RealTime HCV assay (Abbott Molecular). The genomic region of the HCV 5’UTR was analyzed by nested PCR reaction, with HCV RNA being converted to complementary DNA using the High-Capacity cDNA Archive kit (Applied Biosystems). All procedures were carried out according to the instructions provided by the manufacturer.

e) Evaluation of the expression of key HCV entry receptors Claudin-1 and CD81

We evaluated the expression of Claudin-1 and CD81, key cellular entry receptors used by HCV to infect cells. Flow cytometry and confocal microscopy were used to examine megakaryocytes and platelets receptors. To perform immunophenotyping, monoclonal antibodies were used along with phenotypic markers, as previously described. Specifically, anti-human Claudin-1 Alexa Fluor 488 (clone 2H10D10, RheaBiotech) and anti-human CD81-APC (clone M38, EXBIO) were used.

f) **Statistical analysis**

Descriptive statistical analysis, including means, standard deviations, and ranges (minimum and maximum), was performed with Prism 8 software (GraphPad®).

### III. Results

a) **HCV-infected megakaryocytes and platelets**

Efficient HCV infection of megakaryocytes and platelets was demonstrated in vitro through the detection of viral expression (NS4A) and viral load (mean 34.25 IU/mL) [31]. The objective was to demonstrate the biological event through descriptive analysis. In megakaryocytes, the average percentage of NS4A in the membrane was 51.71% ± 26.72 (range 11.01%-85.96%). For the cytoplasm, this percentage was 75.57%±29.66 (range 26.61%-99.77%) (Figure 1-A). The NS4A MFI in the membrane was 30.23±9.03
Figure 1: In vitro HCV-infected megakaryocytes were examined by flow cytometry and confocal microscopy. The percentage of NS4A expression was 51.71%±26.72 (range 11.01%-85.96%) in the membrane and 75.57%±29.66 (range 26.61%-99.77%) in the cytoplasm. In the membrane, the mean fluorescence intensity (MFI – absolute value) of NS4A was 30.23±9.03 (range 19.11-43.71), while in the cytoplasm, the MFI was 63.32±32.41 (range 21.29-107.5).

The expression of intracellular viral NS4A was 2.09 times higher than that of membrane NS4A (Figure 1-B), indicating a higher concentration of NS4A or HCV in the intracellular compartment. Supporting this observation, confocal microscopy images showed the presence of NS4A on the megakaryocyte membrane (Figure 1-C1), along with CD61 (a megakaryocyte characterization marker) (Figure 1-C2) and 7AAD (a nuclear marker) (Figure 1-C3). By examining the Z-axis (depth) of the cells, we observed a high brightness density of NS4A expression inside the cell (Figure 1-C4), corroborating the findings from the flow cytometer analysis.

In vitro infected platelets expressed NS4A on both the membrane (47.89%±11.66, range 37.22%-63.85%) and cytoplasm (75.41%±8.36, range 68.73%-86.43%), similar to what was observed in megakaryocytes (Figure 2-A). The NS4A MFI was higher inside the cell (40.82±9.37; range 32.2-53.28) than in the membrane (18.32±2.89; range 15.12-21.29) (Figure 2-B). The expression index NS4A in the cytoplasm was 2.22. Confocal images of in vitro infected platelets showed co-expression of NS4A and CD61 on the surface and in the cytoplasm of the cells (Figure 2C).
Platelets infected with HCV were evaluated in vitro using flow cytometry and confocal microscopy. The percentage expression of NS4A (A) was observed in the membrane (47.89%±11.66, range 37.22%-63.85%) and in the cytoplasm (75.41%±8.36, range 68.73%-86.43%). The median fluorescence intensity of NS4A (B) in the membrane (18.32±2.89, range 15.12-21.29) and in the cytoplasm (40.82±9.37, range 32.2-53.28) indicated an increase ratio of 2.22. The confocal images (C) obtained show the expression of NS4A in yellow (1), CD61 in red (2), and the overlay of both (3). PLT: platelet; MFI: mean fluorescence intensity.

To analyze viral expression in platelets in vivo, we evaluated samples from HCV-positive patients with detectable viral loads (n=2). Patient 1 had an HCV genotype 3 and a viral load of 17.051 IU/mL (4.23 log). Patient 2 had genotype 1B with a viral load of 3.243.950 UI/mL (6.51 log). According to the in vitro findings, platelets express higher viral concentrations in the cytoplasm compared to the cell surface. The results of the histological evaluation demonstrated the co-expression of CD61 and NS4A in liver tissue from HCV+ patients (Figure 3), reinforcing the idea that platelets can carry the virus and serve as extrahepatic reservoirs.

Figure 2: Platelets infected with HCV were evaluated in vitro using flow cytometry and confocal microscopy. The percentage expression of NS4A (A) was observed in the membrane (47.89%±11.66, range 37.22%-63.85%) and in the cytoplasm (75.41%±8.36, range 68.73%-86.43%). The median fluorescence intensity of NS4A (B) in the membrane (18.32±2.89, range 15.12-21.29) and in the cytoplasm (40.82±9.37, range 32.2-53.28) indicated an increase ratio of 2.22. The confocal images (C) obtained show the expression of NS4A in yellow (1), CD61 in red (2), and the overlay of both (3). PLT: platelet; MFI: mean fluorescence intensity.

Figure 3: Viral expression in platelets in liver fragments from HCV patients: histological analysis using fluorescent markers. 1) Expression of NS4A on platelet surface; 2) CD61, platelet marker; 3) Overlay of NS4A and CD61. The arrows indicate HCV+ platelets in the blood vessels.
b) Megakaryocytes express claudin-1 and CD81, whereas platelets express only claudin-1.

The main entry receptors associated with HCV infection are claudin-1 and CD81 [32,33]. In this study, both HCV-infected and uninfected megakaryocytes showed expression of these receptors. Claudin-1 was expressed in 79.47%±10.42% of HCV-infected megakaryocytes (with an MFI of 27.97±5.97) and 69.75%±26.49% of uninfected megakaryocytes (MFI 21.24±7.04). CD81 was expressed in 61.10%±14.05% of HCV-infected megakaryocytes (MFI 220.89±193.95), and 67.56%±13.39% of uninfected megakaryocytes (MFI 105.47±86.46). It is important to emphasize that the in vitro infection process did not induce loss of expression of these receptors, as there was no significant difference between uninfected and infected megakaryocytes (Figure 4A, 4B, 4D). However, higher rates of CD81 (MFI) receptors in the presence of the virus suggest the involvement of immunomodulatory mechanisms.

Platelets expressed claudin-1 and were negative for CD81, confirming the expected phenotype. For in vitro infected platelets, the mean claudin-1 expression was 47.16%±10.36% and MFI was 17.65±4.37, whereas claudin-1 expression in uninfected platelets was 44.83%±8.26% and MFI was 16.36±1.27 (Figure 4C).

CD81, also known as TAPA-1, has four transmembrane domains that play a role in structural adhesion, activation, proliferation, and cell differentiation. According to microscopy images, the membranes of megakaryocytes expressed CD81, highlighting some cell regions with clusters forming structures known as tetraspanin-enriched microdomains. These microdomains are highly dynamic areas on the cell surface that facilitate interaction with other membrane components, crucial for the entry of HCV (Figure 4D-3) [33-34].

Unlike megakaryocytes, platelets expressed claudin-1 and are negative for CD81. For platelets infected in vitro with HCV, claudin-1 expression was 47.16%±10.36% (range 37.08%-57.89%) and MFI was 17.65±4.37 (range 13.7-23.5). Uninfected platelets (exposed to HCV-negative plasma) showed a claudin-1 expression of 44.83%±8.26% (range 33.07%-52.42) and an MFI of 16.36±1.27 (range 14.86-17.94) (Figure 4C). There was no significant difference in claudin-1 expression between HCV-infected and uninfected platelets. Confocal analysis showed a homogeneous distribution on the platelet surface (data not shown).

Figure 4: Expression of Claudin-1 and CD81 in megakaryocytes and platelets. (A) Percentage expression of claudin-1 (left) in infected megakaryocytes 79.47%±10.42% (range 70.46%-94.07%) and uninfected megakaryocytes (control) 69.75%±26.49% (range 46.26%-95.24%) and CD81 (right) in infected megakaryocytes 61.10%±14.05% (range 46.26%-95.24%).
IV. Discussion

HCV was detected in both the surface and the interior of megakaryocytes, with clear areas of higher virus concentration. These findings confirm that megakaryocytes are susceptible to HCV. They expressed high levels of CD81, the major viral entry receptor. Furthermore, molecular analyses have shown that megakaryocytes can support viral replication by detecting the complementary strand of viral RNA. This corroborates previous studies [2,22,35,36] and characterizes the virus-permissive cell function.

Our results regarding viral expression on the surface and cytoplasm of megakaryocytes strengthen our hypothesis that HCV can infect platelet precursors. This suggests that the virus may be transmitted during the differentiation of megakaryocytes into proplatelets, generating infected young platelets, such as swine flu [37]. Our results align with those of Li et al., who studied thrombocytopenia in patients with hepatitis C [2]. They demonstrated that megakaryocytes from a patient with megakaryoblastic leukemia in vitro infected with HCV were permissive to the virus [2]. Moreover, electron microscopy analyses revealed that the virus tends to accumulate around the Golgi complex and vesicles present in megakaryocytes [2]. Our observations using confocal microscopy, which identified areas of higher virus concentration in megakaryoblastic, corroborate these findings.

Several cell lineages, including hepatocytes and megakaryocytes, present CD81 receptors. These molecules are distinguished from other transmembrane proteins by the presence of conserved regions in their extracellular domains. These regions enable CD81 receptors to associate with other proteins such as integrins, signaling molecules, and homo- and heterodimer proteins to form tetraspanin-enriched microdomains [38,39,40]. These microdomains are coordinator molecules required for molecular trafficking, cell-cell fusion, motility, and signaling. Pathogens such as HCV and HIV use them as a gateway into the cell, facilitating viral entry [38-34].

The presence of HCV in the bone marrow correlates with the level of circulating viremia. Bone marrow changes such as hypo- and hypercellularity of erythroid, lymphoid, and myeloid lineages are attributed to factors such as viral load, viral subtype, immune status or immune complex deposition [19,22,36]. Abou El Azm et al. reported a decrease in the megakaryocyte population, the appearance of micromegakaryocytes, and abnormalities in the proliferation and differentiation of hematopoietic stem cells [41]. These observations suggest that HCV can interact directly with these cell populations and contribute to peripheral thrombocytopenia [22]. Similarly, El-Barbary et al. (2010) found a decrease in megakaryocytic colony-forming units and thrombocytopenia in HCV+ patients [42]. Since we have shown that megakaryocytes are permissive for HCV infection, we can infer that the bone marrow may be the extrahepatic site of viral replication.

HCV infection impairs the functions of hepatocytes, the major producers and secretors of thrombopoietin, a growth factor involved in platelet control and formation. Thrombopoietin reduction directly affects megakaryocyte ploidy and development, reducing platelet production. The presence of viral RNA in megakaryoblasts and megakaryocytes further promotes thrombocytopenia. This can occur through cell death or via reduction of the thrombopoietin receptor c-Mpl (myeloproliferative leukemia protein) [2,43,44]. The interaction between megakaryocytes and HCV also facilitates the imbalance in circulating thrombopoietin levels due to the lack of consumer cells for this factor. Consequently, serum thrombopoietin levels are significantly higher in patients with chronic hepatitis C [42].

The presence of HCV in platelets was confirmed here and in previous in vitro and in vivo studies [14,24]. Furthermore, when analyzing the viral RNA in plasma and platelets of HCV-positive patients over 144 hours, there was a decrease in plasma viral concentration, while RNA levels in platelets remained the same [23]. This suggests that HCV can persist in the body for long periods when associated with platelets, which can be considered a viral reservoir. Here, we showed for the first time that platelets express HCV both on the surface and inside the cell. Since the virus does not express CD81, the major receptor involved in HCV infection [32,33,34,38,45,46], the primary question is how the virus infects the platelets.

The mechanism of HCV entry or interaction in platelets is still unknown. Studies have found that cells expressing CD81 (t-Molt4 cells) and those lacking this marker (pro-monocytic lineage U937 and platelets) exhibit similar binding rates to HCV [24]. This indicates that HCV can interact with cells in the absence of the CD81 receptor. HCV may interact with platelets through adsorption or association with adhesion molecules such as anti-human platelet antigen (HPA)-1 integrins [14,47]. This interaction could occur through platelet antigens...
such as HPA-5b and HPA-1B, as their abundance is altered in platelets from hepatitis C patients [14,48]. Another interaction pathway may be through the glycoprotein VI receptor [37]. This receptor is a type 1 membrane glycoprotein belonging to the immunoglobulin (Ig) family with two Ig-C2 domains expressed on the membrane surface of platelets and megakaryocytes. IgG molecules associated with HCV could bind to the Ig-C2 domain, promoting not only cell-cell interaction but also viral dissemination and persistence [14,37,49].

Claudin-1, a junctional protein located on the apical and basolateral surfaces of hepatocytes, is an important receptor for HCV entry into these cells. Therefore, we investigated whether platelets and megakaryocytes express this protein. Claudin-1 functions either directly by binding to CD81 or through cell-to-cell infection. Due to its cellular location, claudin-1 may be able to interact with HCV [50,51]. Our data showed that megakaryocyte cells express claudin-1 and CD81, whereas platelets express only claudin-1. Cells expressing claudin-1 but lacking CD81 are susceptible to HCV [32]. Blocking the HCV-claudin-1 interaction with monoclonal antibodies prevented viral infection in vivo and in vitro, further implicating claudin-1 in HCV infection [33].

Our findings indicate that claudin-1 expression in megakaryocytes is not uniform but rather concentrated in specific areas of the cell. HCV enters hepatocytes through the association between CD81 and claudin-1. This complex facilitates the formation of tetraspanin-enriched microdomains, which are concentrated in certain cell regions. Therefore, we inferred that a similar process of HCV entry might occur in megakaryocytes.

HCV infects hepatocytes either through cell-free particle diffusion followed by engagement with specific cellular receptors or via cell-to-cell direct transmission mediated by mechanisms not well defined yet [52]. Cell-to-cell infection involves direct viral transfer to neighboring cells, allowing the virus to evade immune system cells and antibodies designed to fight it. This strategy may contribute to viral persistence [46,53-55].

CD81, claudin-1, occludin, and low-density lipoprotein receptors are cellular molecules involved in cell-to-cell viral transmission. Since claudin-1 was found to be expressed by platelets even in the absence of CD81, this pathway may be involved in platelet infection [56]. Histological analysis of liver tissue from HCV patients revealed an accumulation of HCV-infected platelets (CD61+NS4A+) around blood vessels. The capillaries or vessels in the hepatic endothelium play a critical role in the exchange of macromolecules, solutes, and fluids from the blood and are also the entry point for pathogens into the liver. We believe that platelets can transport the virus across the endothelium to liver tissue, which could favor the interaction of the virus with different receptors, including CD81, claudin-1, and occludin, allowing viral internalization in hepatocytes [57].

V. Conclusion

This study demonstrated the presence of HCV on the platelet surface and, for the first time, identified viral expression in the cytoplasm of these cells. Possible mechanisms of interaction between HCV and platelets include adsorption due to platelet morphology/phenotype or interaction mediated by receptors such as claudin-1, even in the absence of CD81. Additionally, we demonstrated HCV on both the surface and inside of megakaryocytes, suggesting that platelets derived from infected megakaryocytes may enter the circulation with the virus.

Our findings contribute to understanding the pathophysiology of hepatitis C, especially the interaction of the virus with different cell types. The presence of HCV in megakaryocytes and platelets, either through direct viral interaction that induces apoptosis or by altering the maturation of progenitor cells, may be related to thrombocytopenia, an extrahepatic manifestation often observed in patients with chronic hepatitis C.
